Recent analysis of complete eukaryotic genome sequences has revealed that gene duplication has been rampant. Moreover, next to a continuous mode of gene duplication, in many eukaryotic organisms the complete genome has been duplicated in their evolutionary past. Such large-scale gene duplication events have been associated with important evolutionary transitions or major leaps in development and adaptive radiations of species. Here, we present an evolutionary model that simulates the duplication dynamics of genes, considering genome-wide duplication events and a continuous mode of gene duplication. Modeling the evolution of the different functional categories of genes assesses the importance of different duplication events for gene families involved in specific functions or processes. By applying our model to the *Arabidopsis* genome, for which there is compelling evidence for three whole-genome duplications, we show that gene loss is strikingly different for large-scale and small-scale duplication events and highly biased toward certain functional classes. We provide evidence that some categories of genes were almost exclusively expanded through large-scale gene duplication events. In particular, we show that the three whole-genome duplications in *Arabidopsis* have been directly responsible for >90% of the increase in transcription factors, signal transducers, and developmental genes in the last 350 million years. Our evolutionary model is widely applicable and can be used to evaluate different assumptions regarding small- or large-scale gene duplication events in eukaryotic genomes.

Arabidopsis | functional categories | gene retention

Thirty-five years ago, Susumu Ohno (1) outlined the potential role of gene duplication as the driving force behind the evolution of increasingly complex organisms. Recent analysis of complete eukaryotic genome sequences has revealed that gene duplication has indeed been rampant (2–4). Furthermore, many eukaryotic organisms had their whole genome duplicated, sometimes more than once (5, 6). In particular such large-scale gene duplication events have been considered of major importance for evolution and increase in biological complexity (1, 7–10).

Lynch and Conery (2) were among the first to investigate the overall degree of gene duplication and gene loss in completely sequenced genomes. When the number of duplicated pairs of genes is plotted against their age, inferred from the number of synonymous substitutions per synonymous site (K_S), the resulting age distributions exhibit a typical L shape, with many recently duplicated genes and much fewer older duplicates. Based on these age distributions, Lynch and Conery (2) suggested a steady-state stochastic birth–death model for the dynamics of duplicate populations, from which they inferred the overall rate of gene duplication and gene loss. However, the gene birth and death model proposed by Lynch and Conery (2) does not take into account larger-scale gene duplication events, such as paleopolyploidy events.

Here, we propose a generally applicable evolutionary model that simulates the birth and death of genes based on observed age distributions of duplicates, considering small-scale, continuously occurring local duplication events (hereafter referred to

as 0R) and duplication events affecting the whole genome. In the present study, this model is applied to the *Arabidopsis* genome. There is compelling evidence based on the identification and delineation of intergenomic homology and phylogenetics that the *Arabidopsis* genome has been duplicated three times (events hereafter referred to as 1R, 2R, and 3R) during the last ≈ 350 million years (11–14). Because *Arabidopsis* has undergone several well documented rounds of genome duplication, it is an ideal model system to study gene retention that occurs after ancient polyploidy events versus small-scale gene duplication events. Furthermore, by applying this computational model to different functional categories of genes, we can assess the importance of different gene duplication events for the evolution of specific gene functions or biological processes and pathways.

The aims of our study were fivefold: (i) to develop an evolutionary model that can take into account whole-genome duplication events in addition to the continuous mode of duplication, (ii) to use this model to investigate whether there is a difference in gene loss for genes created during small-scale (continuous) or large-scale (global) duplication events, (iii) to investigate whether duplicated genes indeed form a functionally biased set in small-scale and large-scale gene duplication events, (iv) to investigate whether gene decay and gene retention were similar for the successive whole-genome duplication events in *Arabidopsis*, and (v) to infer the number of *Arabidopsis* genes before the gene and genome duplication events considered in the present study.

Methods

Identification of Paralogs. An all-against-all protein sequence similarity search was performed by using BLASTP (with an E -value cutoff of e^{-10}) (15). Sequences alignable over a length of 150 amino acids with an identity score of 30% were defined as paralogs, according to ref. 16. Gene families were built through single-linkage clustering.

Dating of Paralogous Gene Pairs. Synonymous substitutions do not result in amino acid replacements and are, in general, not under selection. Consequently, the rate of fixation of these substitutions is expected to be relatively constant in different protein-coding genes and, therefore, to reflect the overall mutation rate. As a result, the fraction of synonymous substitutions per synonymous site (K_S) is used to estimate the time of duplication between two sequences. All pairwise alignments of the paralogous nucleotide sequences belonging to a gene family were made by using CLUSTALW (17), with the corresponding protein sequences as alignment guides. Gaps and adjacent divergent positions in the alignments were removed. K_S estimates were obtained with the CODEML program (18) of the PAML package (19). Codon frequencies were calculated from the average

Abbreviation: GO, Gene Ontology.

estimates. Confidence intervals for the parameters α_i were calculated based on the covariance matrix for the best fit (see *Supporting Methods* and Table 2). GO Slim categories with more than two low-confidence parameter estimates were discarded in all further analyses (colored gray in Figs. 5 and 6; see also Table 2).

Results and Discussion

The age distribution of all duplicated genes of *Arabidopsis*, including all 3,472 gene families (see Table 1), clearly shows two peaks or waves (Fig. 1), of which the youngest can be attributed to the youngest duplication event (12–14), whereas the second wave corresponds to the two older genome duplications (12, 13) that have become almost indistinguishable (see below). In previous studies, the second wave had been missing mainly either because large multigene families had been excluded from the analyses (2) or because only small K_S values had been considered (20). As shown earlier, many of the genes in these waves lie in so-called paralogs, i.e., intragenomic homologous segments (12–14). However, many duplicates that originated from large-scale duplication events are found outside those paralogs, particularly for the older genome duplication events, because of gene translocation events. These duplicates were largely ignored in previous studies (24, 25) because they cannot be distinguished from duplicates generated in the continuous mode. In our model, this problem is circumvented by simulating, rather than enumerating, the number of duplicates generated in each duplication mode, regardless of whether they belong to paralogs.

The Functional Landscape of the *Arabidopsis* Paranome. To investigate the relative impact of small-scale and large-scale gene duplications on different functional categories of genes in *Arabidopsis*, we subdivided the global K_S distribution according to the GO Slim ontology (21). Based on the current status of the GO annotations and on the robustness of the age distributions for different thresholds (see *Supporting Methods* and Fig. 7), we chose to add individual gene families to a particular GO Slim category distribution if >20% of the genes in the family were assigned to that category. Despite using a 20% threshold for individual gene families, the minimum overall percentage of genes in a GO Slim class distribution that are annotated accordingly in GO is 58% (for the “carbohydrate binding” category) (Table 1). We do recognize the risk of assigning gene families to a particular GO Slim function or process that are only partially involved in that function or process. Although we found no direct evidence of such cases, the K_S distribution for, e.g., the “response to abiotic stimulus” category should be considered as the K_S distribution for gene families that during their history have been important in the evolution of the response to abiotic stimulus rather than the distribution for duplicate genes involved in the response to abiotic stimulus *sensu stricto*. The size of the gene families, the total number of genes ascribed to a functional category based on these gene families, the proportion of those genes directly annotated by GO to that functional category, and the number of retained duplicates and the estimated number of ancestral genes for that functional category can be found in Table 1.

Modeling Gene and Genome Duplications. To quantify the differences in K_S distribution between the GO categories, a population dynamics model was developed that is able to accurately reproduce the observed K_S distributions and characterize them in terms of only a few parameters. The model itself is described in detail in *Methods*, but the principal assumptions and potential shortcomings of our model will be considered here. Because the calibration of time since duplication versus K_S is controversial [see, for example, Lynch and Conery (2) and Koch *et al.* (26), who propose quite different rates of synonymous substitutions in

dicots], all calculations were performed based on K_S time equivalents without explicit conversion to real time (*Supporting Methods*). Throughout the manuscript, time since duplication is therefore expressed in K_S time equivalents. The simulation starts at time step 1 (5.0 K_S time equivalents ago) from a number of ancestral genes G_0 (*Supporting Methods* and Table 1) and evolves this ancestral genome to the present-day size by gene duplication and gene loss, thereby creating a simulated K_S distribution. Four distinct modes of gene duplication are included, namely a continuous mode of small-scale gene duplication (0R) and three large-scale duplication modes (1R, 2R, and 3R). We assume that small-scale duplications in the continuous mode occur at a constant birth rate ν (see *Supporting Methods*). Local fluctuations of the birth rate ν with time are averaged out over longer time periods. Systematic deviations from a constant birth rate (e.g., systematic increase of birth rate with time) or prolonged time periods with a significantly altered birth rate would be reflected by the inability of our model to reproduce the observed K_S distribution. In our case, it proved to be unnecessary to make more elaborate assumptions (Occam’s razor). The average birth rate ν of new duplicates was estimated to be 0.03 per gene and per 0.1 K_S time equivalent based on optimization of the model fit to the whole paranome K_S distribution for several values of ν (Fig. 9, which is published as supporting information on the PNAS web site). Our estimate is about twice as high as the one proposed by Lynch and Conery (27).

On top of the continuous duplication mode, we have modeled three whole-genome duplications occurring at time steps $t_i = 20, 31, \text{ and } 44$ in the simulation (respectively 3.1, 2.0, and 0.7 K_S time equivalents ago). These values correspond to the three previously described large-scale duplication events in the evolutionary past of *Arabidopsis* (12, 13). The ages of the whole-genome duplications were estimated through simulations of the duplication history of the whole paranome for different age values. These ages were subsequently used throughout the simulations for all GO Slim categories. A model based on only two large-scale duplications, assuming that 1R did not take place, gave considerably worse fits (Fig. 2 *A* and *B*), again providing evidence that three large-scale duplications have, indeed, occurred in the evolutionary past of *Arabidopsis*. The model is able to compensate in part for the lack of genes created by 1R by increasing the retention of duplicates in the continuous mode (lower decay parameters α_0), especially for GO categories with moderate to low retention after 1R, such as the “whole paranome” category. However, categories with a high retention subsequent to 1R, such as “development,” show pronounced bias in the residuals. We also assumed that the three large-scale duplication events were complete genome duplications. Although for the youngest event there is substantial evidence that at least 80% of the genome was duplicated (12–14), it is very difficult to assess whether the older large-scale duplication events were also genome-wide. The validity of our assumption can, at least to some extent, be examined by modeling alternative assumptions. For example, if we assume that the second large-scale event (2R) only affected half of the genome, the effects thereof will propagate to later time points (smaller K_S), by means of the coupling of all duplication modes. More specifically, the continuous mode of duplication will then have acted on considerably less genetic material right after 2R, resulting in the inability of the model to reproduce the duplicate count observed in the actual K_S distribution between $K_S = 1.0$ and 2.0, after 2R (Fig. 2*C*). This effect is more pronounced for GO categories with a low decay rate (or high retention) in the continuous mode. The 2R peak itself ($K_S > 2.0$) is still fitted reasonably well by lowering the 2R decay parameter α_2 .

The duplicates created during the whole-genome duplication events and the continuous mode of duplication are lost with mode-specific time-dependent decay rates α_i/t ($i = 1$ for 1R, $i =$

Fig. 2. Optimal fits and parameters α_i (Upper) and residual errors (Lower) for the “whole paraneome” and “development” GO categories, simulated under various model assumptions. (Upper) The green curves show the observed K_S distributions, and the blue curves represent the simulated K_S distributions. (Lower) The residual error is defined as the difference between the observed and the simulated distributions. Biased residual errors, meaning that they are consistently positive or negative for prolonged K_S intervals, hint at unrealistic model assumptions. (A) Model fits under the assumption that there were three whole-genome duplications and that gene decay follows a power law. The residual errors show very little bias. (B) Model fits under the assumption that 1R did not occur. (C) Model fits under the assumption that 2R was partial and involved only 50% of the genome. (D) Model fits under the assumption that the number of retained duplicates decays exponentially.

2 for 2R, and $i = 3$ for 3R) and α_0/t (0R), respectively. A decay rate α_i/t leads to a decay of the power-law form: $D_i(t) = D_i(0)t^{-\alpha_i}$, where $D_i(t)$ represents the number of duplicates in the i th duplication mode after a time t . Compared to an exponential decay with a constant decay rate α_i , as suggested by Lynch and Conery (2), a power-law decay exhibits a flattened tail. We observed that an exponential decay model could not adequately reproduce the observed K_S distributions, in particular for high K_S values (Fig. 2D). Also, decay parameters α_i obtained with the exponential model steadily increase with the decreasing age of the duplication mode ($\alpha_1 < \alpha_2 < \alpha_3 < \alpha_0$), which cannot be biologically motivated. Indeed, a constant decay rate is unrealistic from a biological viewpoint. If duplicates have been retained for a longer time, it is more probable that they confer added value or fitness to the organism, which reduces their chance of being lost (28). In other words, the decay rate should asymptotically tend to zero for increasing time since duplication. This scheme allows for rapid initial gene loss that gradually evolves toward a preferential retention of older duplicates under selective constraints.

Small-Scale Versus Large-Scale Duplications and Biased Retention of Duplicates. Gene decay rates were estimated by the model through fitting of the age distributions drawn for the different functional categories (Figs. 5 and 6). Fig. 3 shows examples of the four different decay parameters, namely those for 0R, 1R, 2R, and 3R, for some specific GO classes, such as transcription, development, and secondary metabolism. A table with the decay parameters for other functional categories and for confidence values for these parameters can be found in Table 2. A clustered color representation of gene decay is shown in Fig. 4 for all GO classes that could be modeled adequately (evaluated based on confidence intervals; see Table 2).

One of the most striking observations is that, for many functional categories, gene decay rates differ considerably for genes created during large-scale (1R, 2R, or 3R) and small-scale (0R) duplication events. As a matter of fact, for a majority of GO Slim categories, an almost opposite picture is obtained for genes created during whole-genome or small-scale duplication events. Probably most prominently, gene decay is low for genes involved in kinase activity, transcription, protein binding and modifica-

Fig. 3. Observed (blue line) versus simulated (green and yellow surface areas) K_S distributions for some GO classes discussed in the text. The parameters in the upper right corners of each graph specify the simulated decay rates for the continuous mode of gene duplication (α_0) and for the whole-genome duplications 1R (α_1), 2R (α_2), and 3R (α_3) and their confidence intervals (Table 2). The colored areas show the simulated fraction of retained duplicates created by each duplication mode as a function of K_S . Similar graphs for other functional classes can be found in Fig. 10, which is published as supporting information on the PNAS web site.

tion, and signal transduction pathways when created in large-scale gene duplication events, whereas gene decay is very high for such genes when created by individual, small-scale duplication events (Fig. 4). Accordingly, Blanc and Wolfe (24), considering only the most recent polyploidy event in *Arabidopsis*, also observed a high retention of genes with regulatory functions, such as transcription factors, kinases, phosphatases, and calcium-binding proteins. Seoghe and Gehring (25) also found that genes involved in transcription regulation and signal transduction had a significantly higher survivability after genome duplication than other functional categories. Rapid loss of these duplicated genes after small-scale gene duplication events may be explained by the fact that regulatory genes involved in signal transduction and transcription tend to show a high dosage effect in multicellular eukaryotes (29). That transcription factors and kinases are often active as protein complexes and need to be present in stoichiometric quantities for their correct functioning is congruent with their high retention rate after whole-genome duplication events in contrast to small-scale duplication events (30, 31). On the other hand, genes belonging to other functional categories show a markedly different behavior and are retained in excess after large-scale and small-scale duplication events. Examples are genes involved in secondary metabolism and response to biotic

Fig. 4. Clustered color representation of the decay parameters for all duplication modes and GO Slim categories. Light blue corresponds to high gene decay or low retention, and bright yellow corresponds to low decay or high gene retention. The numerical values and confidence intervals of the decay parameters can be found in the supporting information. The decay parameter of 0.70 (black) was chosen to match the continuous-mode decay for the whole paraneome. P denotes the Biological Process categories, and F denotes the Molecular Function categories.

stimulus. Because plants are sessile organisms, secondary metabolite pathways and genes governing the response to biotic stimulus have been crucial to develop survival strategies against herbivores, insects, snails, and plant pathogens (32). The low decay rate of these genes in small- and large-scale duplication modes (Fig. 4) furthers the evidence that secondary metabolites represent important adaptive traits that are heavily selected for during evolution to protect plants against a wide variety of enemies imposing a constant need for adaptation. Genes in-

volved in conserved biological processes are generally little retained (Fig. 4). Examples are DNA metabolism genes (which includes DNA repair, DNA replication, and DNA recombination), ribosomal genes (except for 3R), nucleases, RNA binding genes, and (to a lesser extent) cell cycle genes and protein and macromolecule biosynthesis genes. Our model also shows that gene decay is not the same for different whole-genome duplication events, although the general trends are similar. For instance, gene decay occurring after the youngest duplication event (3R) seems to be higher (Fig. 4, blue coloring in the whole paranome row at column 3R) and less biased toward functional class (Fig. 4, less deviation from the mean reflected by an overall darker coloring in column 3R) than for 1R and 2R. In particular, genes encoding transcriptional regulators and genes involved in development are better retained after the second genome duplication event than after the other duplication events. This finding seems to be congruent with what is known about the rise and early diversification of the angiosperms, but this result will be discussed elsewhere.

The impact of small- and large-scale duplications on the expansion of specific functional categories of genes becomes even clearer when we consider the actual numbers of genes retained subsequent to 0R, 1R, 2R and 3R. Based on integration of the mode-specific K_S distributions (Fig. 3, colored areas), we estimate that the three genome duplication events are directly responsible for $\approx 90\%$ of all transcription factors in higher plants created in the last ≈ 350 million years (roughly corresponding to $K_S = 5.0$) (Table 3, which is published as supporting information on the PNAS web site). Similarly, we estimate that 1R, 2R, and 3R taken together account for 92% of all developmental genes and 99% of the kinases and genes involved in signal transduction created since the time corresponding with a K_S value of 5.0. For most categories related to metabolism, stress response, or cell death, the percentage of large-scale gene duplicates ranges from 50% to 70%, reflecting the fact that these categories show relatively higher gene retention after small-scale gene duplication events.

From the simulation results, we can also infer the number of genes that was initially created in each mode. We estimate that 17,193 duplicates were created by 1R, of which 771 (or 4.4%) duplicates have been retained; 20,316 duplicates were created by 2R, of which 2,765 (13.6%) were retained; and 24,351 duplicates were created by 3R, of which 3,947 (16.2%) duplicates have survived. In contrast, 0R created 33,182 duplicates in the last

350–400 million years (12, 13) and is responsible for 5,266 (15.8%) retained duplicates (see Table 3). It is clear from these numbers that, although a considerable number of genes has been retained after gene duplication, gene loss is by far the most likely fate of duplicate genes. Overall, the three genome duplications in *Arabidopsis* have been directly responsible for $\approx 59\%$ of the total number of duplicates that have been retained during the last ≈ 350 million years, which means that more than half of the *Arabidopsis* genome expansion, from $\approx 14,800$ genes in the ancestral genome at time point $K_S = 5.0$ (G_0 for the whole paranome in Table 1) to $\approx 27,500$ genes now (from G_0 ; Table 1), is directly caused by genome duplications. Still, $\approx 40\%$ of the genome expansion is caused by gradual accumulation of small-scale gene duplicates.

In conclusion, we have developed an evolutionary model that simulates the population dynamics of duplicate genes created by small- and large-scale duplication events based on their age distribution in a genome. One of the main advantages of our modeling approach is that it provides a means to study gene retention occurring after genome duplications without the need to attribute every gene to a particular duplication event. Applying our model to the *Arabidopsis* genome shows that much of the genetic material in extant plants, i.e., $\approx 60\%$, has been created by ancient genome duplication events. More importantly, it seems that a major fraction of that material could have been retained only because it was created through large-scale gene duplication events (Figs. 3 and 4). In particular, transcription factors, signal transducers, and developmental genes have been retained subsequent to large-scale gene duplication events, in particular, to the second genome duplication (2R), whereas the contribution of small-scale gene duplications to the increase of regulatory and developmental genes has been very limited. Because the divergence of regulatory genes is being considered necessary to bring about phenotypic variation and increase in biological complexity, it is tempting to conclude that such large-scale gene duplication events have indeed been of major importance for evolution in general, as suggested in refs. 1, 7, 9, 10, and 33.

We thank Ken Wolfe, Axel Meyer, Cathal Seoighe, Dirk Aeyels, and Dirk Inzé for critical comments on the manuscript. S.M. is a Research Fellow of the Fund for Scientific Research (Flanders, Belgium). S.D.B. and J.R. are indebted to the Institute for the Promotion of Innovation by Science and Technology (Flanders, Belgium) for a predoctoral and postdoctoral fellowship, respectively.
